Important Safety Information

All safety warnings give specific details of the potential danger/warning present and indicate how to reduce risk of injury, damage and electric shock resulting from improper use of the device. Carefully observe the following instructions:

Installation and maintenance must be carried out by a competent person, in compliance with the manufacturer's instructions, the relevant wiring regulations and local safety regulations. If in any doubt, consult a qualified electrician.

The device must be disconnected from the power supply before carrying out any installation work.

The device must have adequate ventilation. The device must be installed in a vertical position.

Regulations require that the device is earthed.

Do not remove the device cover while the power supply is connected.

Do not operate the device with the cover removed.

Do not attempt to repair or replace any part of the device.

Do not touch the device with any wet part of the body.

All Maintenance operations must be carried out by a qualified technician. This appliance is not suitable for outdoor use.

The manufacturer accepts no responsibility for any damage or injury caused by improper use or failure to comply with these instructions.

Warranty & Disclaimer

Paladin has made every effort to ensure the accuracy of the content of this manual. However, it is possible that it may contain technical inaccuracies or typographical or other errors. Paladin will assume no liability for any inaccuracy found in this publication, nor for damages, direct, indirect, incidental, consequential or otherwise, that may result from such an inaccuracy. The information provided in this manual is subject to change without notice. Paladin reserves the right to alter product designs or specifications without notification.

Document Purpose

This document is intended to provide you, the end user, with an overview over the hot water diverter basic functioning and display settings and to summarise basic steps for in- home trouble-shooting.

Background

The hot water diverter is designed to maximise the value of your solar system by capturing any excess solar power and diverting it to heat your hot water instead of exporting back to the grid.

The device watches the main power line on your home and instantaneously sends the exact amount of power that would have been exported to your tank using a solid-state relay. This allows power to be sent to the tank at any rate from 0-3500 watts as opposed to the normal on/off that the tank would do.

Basic functioning of the hot water diverter

The hot water diverter is designed to re-direct solar power that would otherwise be exported to the grid into your hot water tank. This maximises the value of the power you generate through the solar system as you are using the hot water tank similar to a battery.

The hot water cylinder temperature is monitored to ensure that it never drops below a pre- set temperature. By default, this is 40^oC but can be changed with the Toggle Switch on the top of the diverter. If the tank temperature drops below 40^oC then grid power will be used to bring the tank back to the minimum temperature. Once it has reached the pre-set minimum, it will watch for export electricity and to divert to the tank up to the maximum set temperature of the hot water cylinder. There are two ways the maximum temperature is defined.

The Diverter is pre-set to a maximum temperature of 73^oC. Additionally, all tanks have an adjustable thermostat. At the time of installation, your thermostat will be set to your tanks maximum rated capacity (or other temperature agreed between you and the installer). The lower of these two temperatures will determine the maximum operating temperature of the tank.

Display explanations

The display for THE DIVERTER is not at all important for its correct operation, but there is a host of information there which can be useful.

Here is a brief summary of the display. The deeper explanation can be found below in the FAQs.

The overarching rules for this display are:

- 1. When there is nothing interesting to show, the associated line will be blank.
- 2. When there is no activity on that line, the line will show totals for the day so far if any.
- 3. There is no rounding or smoothing of data. Even the 'noise' is interesting (see FAQ).

The 4-line display can be best described line by line:

Line 1

To the left is the hot water tank temperature in degrees Celsius.

In the centre is either terse words to indicate what is happening now apart from when the diverter is transferring excess solar, when this displays a 'throttle' graphic' to give sense of how hard the diverter is working. On the right is the number of hours | minutes that excess PV transfer has taken place so far today.

Line 2

This is the Grid activity line. This line is always displayed and shows either IN or OUT and a number in Watts. If there is excess PV this will bounce between IN and OUT. Remember these are snapshots of what is happening 3200 times a second internally and the gross values of the numbers while bouncing are not actually what is passing through the meter. When there is no excess PV, it will always show IN. If your hot water is at maximum or you have PV in excess of your heater element, it will show OUT.

Line 3

This shows the Transfer of PV to Hot water data. While there is active PV diversion the line shows 'DIVERT' power in Watts and a 'TOT' with a value in Watt Hours. When diversion stops the line changes to 'X'FERED' and 'TOP' (both in Watt Hours), which shows the total transferred and topped up (from the grid) respectively.

Line 4

This line only shows if you have a second CT fitted to measure solar production. This is just 'info only' and has no effect on the diverter's operation. All Paladin diverters now have this second CT supplied and so this line will display.

Auto/Manual Changeover Switch

The diverter is installed with a 3-way changeover switch. This allows you to bypass the diverter in case the unit fails, needs to be turned off, or malfunctions. This switch or similar is to be supplied by the installer.

Positions are as follows:

AUTO = Hot water diversion device controls the temperature in the hot water tank. The switch should be left in this position for normal operation.

OFF = The diversion device and the hot water tank will be completely off with no electricity passing through to either.

MANUAL = The diverter device is entirely bypassed, and grid power will feed the hot water cylinder. This will return control of the hot water cylinder to the internally installed thermostat, as it was before the installation of the device.

Toggle Switch Function

This switch has 3 positions. LEFT - OFF - RIGHT. This is what it does:

40°C minimum temperature = Centre position

Minimum temperature setting to 40^oC or whatever minimum has been selected on the DIP switches internally. This is the position recommended for normal operation, especially in the summer months when there is plenty of excess solar.

60°C Night Boost = Left position

With the switch in the LEFT position the diverter will boost the water temperature to 60°C in the small hours of the morning, at the time of the daily reset. Depending upon the quality of your hot water cylinder insulation this will leave you water temperature at around 58°C for morning showers etc, to avoid topping up on peak grid power. If the water is already above 60°C when the daily reset occurs, then nothing happens. With the switch in the LEFT position the 'C' appending the displayed water temperature changes to 'B'.

50°C minimum temperature = Right position

Putting the switch RIGHT changes the minimum temperature setting to 50° C (from 40° C). If the water temperature is below 50° C then you will start heating. With the switch in the RIGHT position the 'C' appending the displayed water temperature changes to '^'.

Either the LEFT position or the RIGHT position may be used when the user is not getting enough hot water. This may occur:

- There are high losses from the system overnight (poor cylinder insulation)
- There is high morning hot water demand
- A small solar system is installed
- During winter months when solar generation is lower

Be sure to set the Toggle Switch position back to the centre when the above conditions do not apply. The Centre position maximised transfer and therefore allows the diverter to do what it is designed to do—i.e. minimise grid electricity use to heat hot water.

FAQ

Why do the numbers 'bounce' and the PV Totals not match the Inverter?

The diverter is not designed to be a meter as its core task is to figure out what is happening at the grid entry point and divert every possible Watt of excess PV to the hot water cylinder. The dynamics of the electricity flow to and from a house are complex and chaotic, and depending upon the observation time frame the relationship between PV and house activity is either serene or very variable. The diverter reads that electron stream as fast as possible to get an accurate sense of what is happening every mains cycle (one fiftieth of a second) and acts on that information in the same time scale. It also continuously changes internal values to cater for varying conditions. The diverter's short-term accuracy is high; long term 'metering', not so much - by design.

With that in mind you will see the Grid values 'bouncing' since that number is updated once a second and it represents a snapshot of 1 second's worth of averaged activity. Hidden inside that 1 second number is another 50 cycles worth of activity and 3200+ grid reads.

Likewise, any totals are just an approximation of what has happened since the last reset. These numbers are not absolutes and are provided for the user to get a sense of the day's progress, not as a substitute for a meter reading. Your electricity meter and PV inverter data are the correct place to look for absolute values. That said, there should not be a huge difference and any large deviations should be investigated as it could indicate a badly placed or defective CT clamp, or even some problem with the Diverter itself. But again, the diverter is extremely sensitive and often 'sees' effects that are not directly associated with pure household current flow, such as minute induced changes in the house and CT wiring caused by external influences. E.g., high values of solar radiation caused by Coronal Mass Ejections, induction from overhead power lines and such are typical suspects.

An aside on the subject of accuracy—a vacuum cleaner uses more power on the forward than on the backwards stroke. The diverter is so fast and accurate that it sees that and reacts accordingly. The reason is reasonably obvious once you think about it. Pushing forward, there is a downward component to the applied force, which in turn presses the cleaning head harder onto the floor; thus increasing the seal, and the effort required to spin the motor.

When do the Totals reset?

The diverter's internal clock is linked to solar activity, or more specifically to PV transfer. An hour is still an hour, but the day start time is internally 8 hours since the last PV transfer activity to the hot water cylinder. Nominally this will be around or just after midnight, but in the summer, may be as late as 4am. Since this only affects the Totals, it is of no importance to the diverter's mission, just the displayed totals. Since the totals are about transfer, using 'sun' time is the most practical option.

How does the diverter manage Legionnaire's Disease?

There is a health problem associated with accumulated 'nasties' that breed in water systems that run at temperatures below 50°C or so for prolonged periods. The effective recommended prevention technique is to ensure that the water temperature reaches 60°C at least every 72 hours. The diverter does exactly that. Whenever the water temperature reaches 60°C it resets an internal counter to zero. Every hour it adds one to that counter and if the counter reaches 72 the hot water is boosted to 60°C, at which point the whole cycle starts again. If you have excess PV then this activity will be rare, but there will be times when it happens - particularly in winter. Internally The diverter tries to anticipate this, and if it anticipates a potential 'health top up' occurring during day time peak hours it will forward schedule the temperature boost to 60°C in the early hours of the day, just after the totals reset.

With regard to water temperatures, it should be obvious that if your hot water cylinder main thermostat is defective, not set to maximum or in some other way not able to allow a temperature of at least 60^oC then the health temperature sequence will effectively force the diverter to top up continuously and be totally ineffective.

Likewise, if the temperature probe is incorrectly positioned a similar situation will occur.

How accurately does the diverter transfer excess PV?

There are a couple of 'Ifs' associated with the answer. If your excess PV never exceeds your hot water heating element rating and you never reach 73°C water temperature or your tank thermostat limit then you can expect 90%, often 95% or sometimes even better. The 'even better' bit depends very much on the type of loads that occur in the house and the gross variability of the PV output itself. Typical 'difficult' loads for the diverter to manage are high wattage irons and Induction cookers. The diverter does manage these rather well, but the very rapid surges in load that they produce can cause small amounts of 'spillage'. Once you produce excess PV over and above what your cylinder element can absorb, or you hit maximum temperature, excess PV will of course be exported.

DELTA-T Operation?

The diverter introduces a novel concept (for a device like this) of DELTA-T - that is rate of change of temperature over time. This is largely transparent in operation, but the more eagle eyed may see its effects. If the water temperature is dropping quickly towards minimum (40^oC normally) the Delta-T mechanism will see this well before the water actually reaches 40^oC and will start a top up sequence earlier than would be possible by just waiting for 40^oC to be registered. This allows the diverter to head off most cold shower situations, subject to water use and heater size etc. Conversely, when topping up, if there is only a few degrees of temperature to change then Delta-T will not activate the heater at full power.

The device will monitor that DELTA-T value, and uses that as an inverse analogue of your hot water use. Simply put, by watching DELTA-T, the device can anticipate if the tank temperature could fall below the minimum set point in the near future, then ensures that your tank maintains the minimum set point in a range of conditions.

The software then uses DELTA-T to anticipate the tank heater turn on point by changing the Minimum Water Temperature value every 12 seconds to adjust it for a decreasing or increasingly negative DELTA-T. If the tank temperature is above 50°C this creates a Minimum Tank Temperature increase equal to the negative DELTA-T. Below 50°C the DELTA-T influence is doubled. If you are watching your MAX | MIN values, you will see this happening. To avoid over doing this function if there is active Solar, this effect will be moderated if more than 500W of solar activity is perceived. This will ensure that grid power is not wasted heating water that will be heated later by solar.

Recommended system details?

There are some practical and basic limitations to Hot water cylinder setups that can take best advantage of the diverter's abilities:

- A Hot water cylinder of at least 180 litres and a thermostat set above 73⁰C.
- A tempering value that will enable the cylinder water temperature thermostat to be set at more than 60⁰C. (The hotter the water the more power it can store, and the better the buffer for cloudy days).

- 3. If your thermostat does not allow at least 60C in the tank, or if the temperature probe is badly positioned, you will see the word "ELEMENT" appear top centre of the screen when Paladin attempts to do a 60C top-up to run its' Health protocol. In this case Paladin is effectly continuously topping up. Either replace the thermostat, reposition the temperature probe or reset Paladin by powering OFF then ON.
- 4. This reset will reset the internal 72 hour Health Timer and allow normal operation again for the next 72 hours.
- 5. Normal use of hot water. If you are not regularly drawing off hot water then the best that the diverter can manage is about 1.6 KWh of solar power diversion per day, as that is the magnitude of normal thermal losses (see below).

The average household consumes 8 to 12 kWh of electricity a day for hot water. The numbers are: (and individual mileage may vary)

A 180-liter hot water tank uses 3.15kWh of electricity to raise the water temperature by 15 degrees Celsius. A normally insulated 180L tank uses around 1.6kWh of energy per day in lost heat.

The situation is this: If you have a 1:1 FIT you really don't care when your hot water cylinder heater runs. You produce the power, you use the power - the time frame is not important. However, if you are buying power at 4 times the rate you can sell it for, then it makes perfect sense to use as much of your own power as possible at the exact moment you produce it. If the Grid doesn't want your power, then the Grid doesn't get it. Without a large battery, the only practical power storage you have in the average home is the hot water cylinder.

How?

This section is the slightly nerdy stuff that is definitely just 'nice to know', not 'need to know'.

Happily, everyone now has a smart meter installed. All smart-meters work in essentially the same way. They have (conceptually), a 1Wh or 3600 joule 'power bucket' that keeps track of the energy flow. When the 'bucket' fills, for either import or export, the light flashes and the appropriate power counter goes up by 1 unit - usually 1000 units to the kWh. If we monitor the mains feed to the house and collect data fast enough, we can accurately model the state of that 'bucket' and we can leverage that data to switch the hot water cylinder heater on and off just enough to stop the bucket filling, and consequently ticking over the meter. The key here is speed, and you can only practically switch the heater on and off on the crossing phase of the mains cycle, which is 50 times a second.

The 1Wh 'bucket' capacity is a real bonus in this sense. 1Wh doesn't sound a lot, but in other units it is 3600 Joules. This is just another, larger number. However, think about a 1kW heater running for 1 hour. In that time, it uses 1kWh (1000Wh) of energy, give or take. What about each minute? That would be 1000/60 = 16.6Wh. What about every second? That will be 1000/3600 = 0.278Wh. There might be 2 light bulbs above your head at this point? One will be for the 3600, which is, not by coincidence, the number of seconds in an hour and also the number of Joules in a Watt.

The second, and most important, is that the power use on a 1kW heater every second is a fraction of the 1Wh of the 'bucket'. Even a large 3kW hot water cylinder element uses less than 1 Watt per second. How convenient is that?

The diverter can control your element on and off up to 50 times per second (Hz), at the mains frequency. Additionally, it is monitoring the mains flow, over 60 times per mains cycle - which is >3000 times per second.

So, a simple metaphor for the diverter's operation would be a water tank, filled by your solar at a variable rate dependant on the panel output, and emptied by the amount of power use in the home. At the bottom of the tank is a large tap that represents your hot water cylinder element. The diverter watches, calculates and waits until the tank is half full. It then opens the tap to the element. Depending upon the rate of input flow, the tank either begins to empty or continues to fill. If the tank starts to empty, then the tap gets turned off.

Otherwise it stays on for another cycle. If the solar input exceeds the tank capacity and the flow to the element then it will eventually fill, and you will just have to export that Watt of power, and the cycle starts again.

In practice, if you have a solar array that is significantly larger than your heater and not much power use in the house in the middle of a summer's day, you are going to export power. But only the remainder and it is unavoidable.

The good news is that this doesn't happen that often because of the shape of the solar curve. You will also be forced to export if your tank temperature reaches maximum, obviously.

At this point, just to stay a little nerdy, it is well to mention that the diverter is not perfect. Despite a very high sampling rate and high-quality sensors, the vagaries of inductive loads, such as the motors / compressors on refrigerators and freezers, power tools and heat exchangers etc, do cause the diverter to miss the odd Watt here and there. In practice, this can be around 5% of excess PV per day in unintended export. It depends on your household use, the variability of the sunshine and the quality of your house wiring.

But to put that in perspective on the same day you will have diverted all the rest to your hot water cylinder element.

Temperature probe

Should the temperature probe be damaged, incorrectly wired or just not fitted, there is a self-check mechanism built into the start-up sequence. If your probe is correct and sending valid temperatures, then you will NOT see the following:

If the probe is not fitted or not working, the start-up sequence will be protracted whilst a full check is carried out. This takes about 20 seconds and the screen indicates marching '>>>'. A failure puts the diverter into a NO TEMP mode. This mode is quite safe to use the diverter in this mode for a few days pending repairs or replacement.

You will have 'NO TEMP' replacing the diverter on the screen and no temperature values on the display. All other diversion functions are as normal.

No hot water?

If you discover no hot water, please check the display of the diverter. If it does not appear to be displaying correctly or it is blank, please reset your diverter. This is done by switching the rotary AUTO-MANUAL Changeover switch from the AUTO position to the OFF position and back to AUTO again. Check that the usual unit starts up and the usual display is showing.

Sometimes the diverter may suffer a software glitch and this reset is usually all that is required to reset it. If the display remains off, then move the Changeover Switch to the MANUAL position. This will bypass the diverter completely and your hot water cylinder will operate with grid power as it used to do before the diverter was installed. If this happens please contact your supplier or Paladin NZ to investigate.

A final word on thermostats:-Below are two daily diagrams from the same house:

The first is NOT Paladin and it should be obvious that the second diagram (PALADIN) is doing a much better job of managing that excess solar. However, look at PALADIN's problem about 12:30. The thermostat tripped and Paladin had to wait until that thermostat reset until it could get back to transferring again. And then after a short while, the thermostat tripped again.

Paladin's normal top temperature is set at 73C. This is about the practical maximum for a generic water tank. However, if your thermostat is tripping before 73C (and most standard ones do), you are not only exporting PV that could go into the tank, but the dwell between the thermostat ON and OFF could be stopping you finishing the solar day with less than an optimally heated water tank.

Talk to your installer. An 85C thermostat is not expensive, and very easy to fit. Set that at about 78C as a backstop and let Paladin do its' best for you.

When the 3 way switch is set to MANUAL, some Paladins will flash the LED screen periodically. This is expected and is not in anyway harmful. However, if this is a problem, an alternate wiring method is available. Please discuss this with your supplier or electrician. Mar 2019
